HIGHLIGHTS

• A new oligoethylene glycol-terminated perfluorinated silane was synthesized.
• The hybrid silane self-assemblies on silica surfaces to form mono- or multilayers.
• The molecular-scale order in films depends on the topography of the substrate.
• Slow kinetics of the silane lattice polymerization result in a monolayer formation.

ABSTRACT

Monolayers of a new hybrid compound having two linearly coupled subunits with different functionalities were prepared on the silicon oxide and silicate-like surfaces using trichlorosilane as an anchoring group. The two subunits of the hybrid compound are a perfluorinated alkyl chain and an oligoethylene glycol chain. The synthesis of the new precursor compound, 0-methyl hexaethylene glycol–icosafluorododecandiol–trichlorosilane is reported starting from commercially available triethylene glycol and perfluorododecan-1,12-diol as building blocks. The final and intermediate products were characterized by nuclear magnetic resonance (1H NMR, 13C NMR, 19F NMR and 29Si NMR), infrared spectroscopy (IR) and high resolution mass spectrometry with chemical ionization [HRMS (CI)]. The new compound was self-assembled on borosilicate glass, surface-oxidized silicon and silicon oxide surfaces. Properties of the self-assembled films as a function of the adsorption time were studied using contact angle measurements, X-ray photoelectron spectroscopy, polarization modulation infrared reflection absorption spectroscopy and scanning force microscopy. The adsorption of the hybrid silane on an atomically flat silica surface lead to the formation of poorly defined multilayer films. By contrast, the adsorption of the silane onto a less-ordered substrate resulted in the formation of a well-packed monolayer.

triazol-linked monolayer produced via copper-catalyzed Huisgen-1,3-dipolar azide-alkyne cycloaddition (so called “click reaction”) [14]. Another approach uses the formation of SAMs from molecules containing two (or more) functional groups as shown in Scheme 1D. While molecules containing different functional groups with precisely designed properties are highly required for modification of complex surfaces, the synthesis of such systems as well as the adsorption process tend to be complicated due to possible reactivities between individual building blocks (anchor group and multiple functional groups). In this paper we report film properties of a new hybrid compound containing two functional groups (Scheme 1D). The hybrid compound contains a methoxy terminated hexaoligoethylene glycol (OEG) unit connected to a perfluorinated alkyl chain anchoring via a trichlorosilane group to the silica surface. The silane chemistry is used to chemisorb the molecule to glass and different silicon oxide (SiOx) surfaces.

Devices fabricated of glass, silicon oxides and silicon nitrides-coated silicon surfaces find numerous applications as implant and biosensor materials [15,16], “lab-on-chips” and microfluidic chips [17,18] and assays platforms for peptide synthesis [19]. Silica nanoparticles are tested as possible drug delivery vehicles [20] or superhydrophobic surface coatings [21]. In those applications, polymers are alternatives to glass and silica material of choice. Despite high costs, glass and silicon oxide remain the most favorable materials due to reproducible fabrication protocols, well understood surface chemistry and biocompatibility [17,18]. However, a non-specific adsorption of proteins as well as cell adhesion (so-called biofouling) may interfere with device performance. Chemisorption of silanes on glass and silica surfaces provokes enormous possibilities of surface modifications aiming at tuning the surface properties of a device [17,22–24]. Surface modifications of glass and silicon oxide surfaces preventing non-specific protein adsorption and biofouling are of large importance for application. For this purpose protein films, polymer coatings [22,23], self-assembled monolayers [24,25] of small amphiphilic molecules and large polymer molecules [26] are commonly used. Molecules containing oligoethylene glycol (OEG) or polyethylene glycol (PEG) units provide the most frequently used coating preventing biofouling [22]. Various modifications or OEG units were tested to allow their chemisorption on gold, silver [27], glass, SiOx, [28,29], indium tin oxide (ITO) [30], oxidized silicon [31] or silicon nitride [32] surfaces.

A perfluorocarbon chain, the second functional group in the new molecule reported here, has good biocompatibility, is lipophobic and shows a high chemical and biological inertness [33–34]. A H-terminated Si(1 1 1) surface modified by a SAM of perfluorinated alkyl chains [35] has significantly reduced friction and adhesion properties. Gentilini et al. [36,37] synthesized an OEG-terminated perfluorinated thioli to passivate Au-nanoparticles. The introduction of a perfluorocarbon chain to the OEG subunit offers new possibilities of the surface modification, which may find numerous biotechnological applications. The particular challenge for this synthesis of hybrid compounds containing a perfluorocarbon chain is due to the strong electron-withdrawing effect of the F atom on the adjacent C atom, making classical nucleophilic substitutions very difficult. In this paper, we report for the first time in the literature the synthesis of a new silane analogue of the thiol reported by Gentilini et al. [36,37] and the formation of monolayers on oxidic surfaces.

1. Introduction

Modification of technologically interesting surfaces by self-assembled monolayers (SAM) represents one important strategy to form chemically well-defined surfaces exhibiting a particular chemical functionality (Scheme 1A). Several reviews are available for such modifications exploiting different chemistries on a number of different substrate surfaces [1–6]. SAMs with more than one functional subunit have been created as patterned monolayers. Such layers expose different functional moieties at different regions of the surface (Scheme 1B). These patterns can be obtained by introducing sequentially two kinds of SAM-forming molecules, for instance by microcontact printing and backfilling [7], local removal-refilling procedures [8,9], local transformation of functional groups of a preformed monolayer [10,11], or by formation/modification of monolayers on pre-patterned and locally addressable substrates [12]. Linearly arranged functional groups may result from sequential build-up of complex surface architectures; i.e. an initially formed reactive surface is chemically modified to obtain a more complex interfacial structure [13]. Typically, the desired function is provided by the functional unit added last to the interfacial system while the other functional groups become linking units (Scheme 1C), for instance, a SAM of

**Scheme 1.** Schematic representation of various SAM systems: (A) a monolayer with one functional group (FG), (B) patterned monolayer containing two kinds of compounds with two FG at different regions, (C) sequential build-up monolayer containing two compounds with two FG and (D) monolayer formed from one molecule containing two FG.

2. Materials and methods

2.1. Materials

1H,1H,12H,12H-perfluoroiododecane-1,12-diol (5) (Alfa Aesar, Karlsruhe, Germany) and dichloromethane (99.9% extra dry,
Acros Organics, Niddereau, Germany) were used as received. All other starting materials and solvents were purchased from Sigma–Aldrich (Steinheim, Germany) as commercial grade and used as received. Preparative column chromatography was carried out using SiO2 (35–70 μm, type 60 A; Merck, Darmstadt, Germany). TLC was performed on aluminum plates coated with SiO2 F254 (Merck). Air-oxidized silicon wafers (Si/SiO2) with a 1000 nm SiO2-layer on a silicon wafer, Borofloat® (BF33) glass wafer, and gold substrates coated with a 10 nm thick layer of chemical vapor deposited silicon oxide (Au/SiO2) were obtained from iX factory (Dortmund, Germany). Silica coating on an oxidized silicon wafer and glass (BF33) were used in order to compare the process of chemisorption of synthesized silicates at pure SiO2 and disordered glass surfaces. Both surfaces have comparable surface roughness and they are flat at the atomic level. Au/SiO2 samples were fabricated according to earlier described procedures [38,39] in order to provide a mirror surface for polarization modulation infrared reflection absorption (PM-IRRA) spectroscopy and a thin SiO2 layer for the attachment of the silanes. The surface roughness of Au/SiO2 surface is close to 1.0 nm and is higher than the surface roughness of the two other materials.

2.2. Instrumentation

Nuclear magnetic resonance spectra were obtained in CDCl3 at 23 °C with a Bruker Avance DRX 500 instrument (500 MHz for 1H, 125 MHz for 13C, 470 MHz for 19F, and 100 MHz for 23Si). Multiplicities of carbon signals were determined with distortionless enhancement by polarization transfer (DEPT) experiments. Infrared spectra were recorded on a Bruker Tensor 27 spectrometer equipped with a “GoldenGate” diamond attenuated total reflection (ATR) unit. High resolution mass spectra (HRMS) were obtained with a Finnigan MAT 95 (CI) spectrometer.

The static water contact angle was measured by the sessile drop method using 2 μL drops of deionized water with the contact angle system OCA 15plus (DataPhysics, Filderstadt, Germany) equipped with a CCD camera and the SCA20 software (version 1.0.0). The quoted values are the average of three measurements on different freshly modified and cleaned samples of Au/SiO2 and BF33 glass wafers.

Modified Si/SiO2 and BF33 surfaces were cleaned as described in Section 2.3.3 and imaged by scanning force microscopy (SFM) in the Tapping mode® using a NanoScope IIIA controller, a Dimension 3100 sample stage and scanner and a TESP tip with a nominal force constant of 42 N m−1 (all Veeco Instruments Inc., Plainview, NY, USA). The measurement of the modified Au/SiO2 surfaces were obtained in the contact mode in water using an Enviroscope with an Enviroscope controller (all Veeco Instruments Inc., Plainview, NY, USA) and a MScT tip with a nominal force constant of 0.03 N m−1 and a resonant frequency of 10–20 kHz (Bruker Corporation, Billerica, MA, USA). Images of 256 × 256 pixel within 1 μm × 1 μm and 5 μm × 5 μm areas were recorded with a scan rate of 1 Hz. Images are shown after background subtraction (“Flattening”) using a first order polynomial using the Nanoscope software (V5.30r3s3r3). Root mean square (RMS) values were determined with this software on a 5 μm × 5 μm region.

X-ray photoelectron (XP) spectra (XPS) were recorded using a PHI 5600ci multitechnique spectrometer (Physical Electronics, Chanhassen, MN, USA) with monochromatic Al Kα radiation (hν = 1486.6 eV) of 0.3 eV FWHM bandwidth. The pass energy of the monochromator was set to 29 eV for the high-resolution spectra yielding a resolution of 0.44 eV. All spectra were obtained using a 400 μm diameter analysis area. During the measurements, the pressure in the main chamber was kept at about 10−9 mbar. The spectra were referenced to the Si 2p peak of SiO2 centered at 103.3 eV [40]. Spectra were analyzed using the XPspEak software (version 4.1). Measured XP spectra are shown as filled circles, the background and the spectral components are thin solid line and the fitted spectrum is a thick solid line.

PM-IRRA spectra were measured with a Vertex 70 spectrometer and an external reflection setup (Bruker, Ettlingen, Germany) containing a poehelelastic modulator (PEM) PMA 50 (Hinds Instruments, Hillsboro, OR, USA). The resolution of the recorded spectra was 4 cm−1. The half-wave retardation (i.e. the maximum PEM efficiency) was set at 2900 cm−1 for the analysis of the CH-stretching modes and at 1100 cm−1 for the analysis of the SiO2 and C2 stretching modes. The incident angle was 80°. The spectra were Min/Max normalized using the OPUS software (version 5.5, Bruker). This method scales the intensity values that the minimum is set to zero absorption units and the maximum intensity to two absorption units.

2.3. Procedures

The synthesis of compound 7, the precursor for SAM formation, is depicted in Scheme 2 and started from commercially available triethyleneglycol monomethyl ether (1). It will be discussed in detail in the next section.

![Scheme 2](image-url)
2.3. Preparation of 4,1,1-trichloro-4,4,5,5,6,6,7,7,8,8,9,9,10,11,12,12,13,13-
Icosafuro-2,15,18,21,24,27,30,33-Octa-1,1-silatetracaitone

While cooling with an ice-water bath, alcohol (6; 105 mg, 0.12 mmol) was added under exclusion of air and moisture (N₂ atmosphere) to SiCl₄ (1.5 mL, 13.1 mmol). The resulting mixture was stirred for 1 h at 70 °C. Then all volatile materials (HCl and SiCl₄) were removed in high vacuum to yield a colorless oil, which consisted of 67% of compound 7 and 33% of byproduct 8 (molar fractions according to integration of the ¹H NMR spectrum). In order to obtain a stock solution for monolayer formation, the material was dissolved in abs. CH₂Cl₂ (c = 0.1 mol/L). Compound 7: ¹H NMR (500 MHz, CDCl₃): δ = 3.36 (s, 3 H), 3.51–3.54 (m, 2 H), 3.60–3.67 (m, 20 H), 3.74–3.78 (m, 2 H), 4.02 (t, J = 14.0 Hz, 2 H), 4.40 (t, J = 12.9 Hz, 2 H) ppm. ¹³C{¹H} NMR (125 MHz, CDCl₃): δ = 58.93 (CH₂), 62.29 (t, J = 28.6 Hz, CH₂), 68.31 (t, J = 25.3 Hz, CH₂), 70.51 (CH₂), 70.58 (5 CH₂), 70.60 (CH₂), 70.61 (CH₂), 70.67 (CH₂), 70.74 (CH₂), 71.94 (CH₂), 72.31 (CH₂), 108.27–109.73 (m, 2 CF₃), 110.20–111.76 (m, 4 CF₃), 112.54–114.39 (m, 2 CF₂), 115.25–116.36 (m, CF₂), 117.37–118.17 (m, CF₂) ppm. ¹⁹F{¹H} NMR (470 MHz, CDCl₃): δ = –123.68 (–123.42) ppm (2 F), –123.25 (–123.08) (2 F), –123.31 (–121.98) (4 F), –121.89 (–121.64) (8 F), –120.94 (–120.79) (2 F), –120.01 (–119.76) (2 F) ppm. ²⁵Si{¹H} NMR (100 MHz, CDCl₃): δ = –35.4 ppm. C₂₅H₃₁Cl₃F₂O₂Si (973.92). Compound 8: ¹H NMR (500 MHz, CDCl₃): δ = 4.36 (t, J = 12.6 Hz, 2 H) ppm, all other signals are isochron with compound 7. ¹³C{¹H} NMR (125 MHz, CDCl₃): δ = 62.06 (t, J = 31.5 Hz, CH₂) ppm, all other signals are isochron with compound 7. ¹⁹F{¹H} NMR (470 MHz, CDCl₃): δ = –121.22 (–121.08) (2 F) ppm, all other signals are isochron with compound 7. ²⁵Si{¹H} NMR (100 MHz, CDCl₃): δ = –53.08 ppm.

2.4. Monolayer formation

Si/SiOₓ, Au/SiOₓ or BF₃ substrates (1.5 cm × 1.5 cm) were cleaned sequentially for 5 min with toluene and isopropanol in an ultrasonic bath and dried in an Ar stream followed by oxidation in an UV/ozone cleaner (BioForce Nanosciences, Inc., Ames, IA, USA) for 30 min in order to create a hydrophilic surface. The clean oxidized surfaces were immersed in 10–15.5 mM solution of the mixture of silanes 7 and 8 (3:2 in absolute CH₂Cl₂ under Ar atmosphere for self-assembly. Depending on the used substrate, the time of the self-assembly process varied from 1 min to 48 h. The substrates were removed from the solution and then rinsed with toluene and cleaned with CH₂Cl₂ and isopropanol in an ultrasonic bath and dried in an Ar stream.

3. Results and discussion

3.1. Organic synthesis

Intermediate products 3 and 4 were reported in literature before [36]. Nevertheless, we have developed an economical and high-yield protocol for compound 3 starting from readily available triethylene glycol monomethylether (1), which was first tosyalted to give sulfonate 2 [94% yield, Scheme 2] and then converted with triethylene glycol to furnish hexamer 3 (86% yield). Another tosylation gave compound 4 [96%]. Thus, the overall yield of this three-step sequence was 79%. Similar to the report of Gentilini et al. [36], who have prepared a corresponding thiol with perfluoroalkyl and oligoethylene glycol subunits, tosylation 4 was converted with an excess of perfluorodiol 5 to obtain the hybrid compound 6, however, the yield remained moderate (59%). This is mainly attributed to the electron withdrawing effect of the perfluorinated moiety which lowers significantly the nucleophilicity of the corresponding alcoholate in the Si₂-type displacement. Anyhow, compound 6 could be conveniently purified by column chromatography and was obtained on a reasonable scale of almost one gram. Then it was treated with an excess of neat SiCl₄ at elevated temperature and alcohol 6 was fully converted. After removal of all volatile materials from the reaction mixture, the residue was analyzed by NMR-spectroscopy, which revealed a composition (molar fractions) of 67% compound 3 and 33% dialkoxysilchlorosilane 8. While the major component of this mixture was unequivocally characterized by ¹H NMR, ¹³C NMR, ¹⁹F NMR, the minor component was identified by the diagnostic triplet at δ (¹H) = 4.36 ppm. The ²⁵Si NMR spectrum of the mixture showed two signals at δ (²⁵Si) = –35.4 ppm (compound 7) and δ (²⁵Si) = –53.1 ppm (compound 8), which were assigned by comparison with the following literature data: δ (²⁵Si) = –38.7 ppm for ETOSiCl₃ and δ (²⁵Si) = –56.1 ppm for (ETO₃)₂SiCl₂ [41]. We were unable to obtain mass spectra of compounds 7 and 8. These reactive silanes cannot be separated. A mixture of 7 (67%, trichlorosilane) and 8 (33%, dichlorosilane with two alkoxyl residual) was used to produce SAMs on silica surfaces. Both compounds are able to chemisorb on the silica surface. Thus, in self-assembled films both compounds 7 and 8 are present. Due to a higher concentration of compound 7 in the solution and presence of three Cl atoms which may undergo oligomerization reaction, one can expect that 7 is the main component of films self-assembled on silica surfaces. However, the ¹H NMR form the densest and best orientated monolayers, due to the formation of three Si–O–Si bonds per molecule [42–44]. According to literature a decrease in the number of chlorosubstituents for long chains in a compound 8 decreases the order of the resulting monolayers [42–44]. It also decreases the reactivity towards the surface.
3. XPS-measurements of monolayers

A monolayer was formed on Si/SiO\textsubscript{2} by immersion in a 15.5 mM solution of 7 and 8 for 3 h. The survey spectrum of the monolayer (Supporting Information, Fig. S1) showed photoelectron signals for Si 2p, Si 2s, C 1s, O 1s and F 1s and Auger peaks of C KVV, F KL\textsubscript{2,3}L\textsubscript{2,3}, F KL\textsubscript{1,2,3}, O KL\textsubscript{2,3} and O KL\textsubscript{1,2,3} in agreement with the elemental composition expected from the sample.

Two significant components were found in the C 1s region (Fig. 1). The first component at 286.6 eV was assigned to \textit{CF\textsubscript{2}} groups and corresponds to the OEG part of the monolayer [32,40]. The second line appeared at 291.6 eV and was assigned to the \textit{CF\textsubscript{3}} groups in the perfluorinated alkyl chain. Moreover, a small C 1s signal at 284.4 eV was observed (Fig. 1). It was attributed to the hydrocarbon contamination (typically around 284–285 eV) [32,45]. Indeed this band was also found at the pure Si/SiO\textsubscript{2} surface and confirms that hydrocarbon signals originated from surface contaminations.

The atomic ratio \textit{N}\textsubscript{(\textit{CF\textsubscript{2}})\textsubscript{2}}:\textit{N}(\textit{CO}) calculated from the high resolution spectrum (Fig. 1) was 1:1.52. For compounds 7 (as well as 8) the expected ratio \textit{N}\textsubscript{(\textit{CF\textsubscript{2}})\textsubscript{2}}:\textit{N}(\textit{CO}) is equal to 1.0:1.5 since the hybrid compound 7 contains 10 C atoms within \textit{CF\textsubscript{2}} groups vs. 12 C atoms in the OEG units plus 1 terminal methoxy C plus 1 C atom linking the OEG part and the perfluorinated chain and 1 C atom adjacent to the silanol group (Scheme 2). The expected and measured ratio of \textit{N}\textsubscript{(\textit{CF\textsubscript{2}})\textsubscript{2}}:\textit{N}(\textit{CO}) were in excellent agreement indicating that indeed the hybrid compound was adsorbed on the silica surface.

One component at 688.7 eV appeared in the XPS spectrum in the F 1s region (Supporting Information, Fig. S1S). Kristalyn et al. [46] and Fréchette et al. [45] found the \textit{CF\textsubscript{3}} signal from perfluorinated silanes at 689.1 and 688.8 eV.

The O 1s region showed a broad signal at 532.9 eV (Supporting Information, Fig. S17), which was deconvoluted into two components. The strong contribution at 533.0 eV was due to the OC at the OEG fragment [32] of 7 (as well as 8) whereas a weak signal at 534.5 eV arose from the O atoms at SiO\textsubscript{2} surface [40]. After removal of the monolayer of 7, the intensity of the O 1s signal at 534.5 eV increased indicating that indeed, it originated from the silica matrix (Supporting Information S12, Fig. S17).

During exposure of the monolayer of 7 to Al K\textsubscript{x} radiation (and resulting secondary electrons), the monolayer spectra changed (Supporting Information S12, Figs. S12–S17). The intensities changes under X-ray radiation did not compromise the functionalities of the layers at solid–liquid interfaces under ambient conditions.

3.3. PMIRRAS measurements

For PMIRRAS measurements, a surface reflecting IR radiation is required. Therefore, Au/SiO\textsubscript{2} substrates were used as analogues to Si/SiO\textsubscript{2} [38]. A 10 nm thick SiO\textsubscript{2} layer provided the OH groups for the chemisorption of silane hybrid compounds while underlying Au served as mirror for the IR radiation. Fig. 2 shows the PMIRRAS spectra in the CH stretching modes region of monolayers of 7 adsorbed on the Au/SiO\textsubscript{2} surface. Due to the presence of the perfluorinated alkane chain, the PMIRRAS spectra of the CH stretching modes originated only from the OEG fragment, i.e. methylene groups adjacent to the O atoms and one terminal methoxy group. As seen in Fig. 2, the intensities of the PMIRRAS spectra increased with time of self-assembly. After 48 h of the adsorption process no further changes in the PMIRRAS spectra of monolayers of 7 on Au/SiO\textsubscript{2} surface were observed. This result indicated that the monolayer formation was slow for compound 7.

The PMIRRAS spectra of SAMs of 7 were composed of several overlapped bands. A weak and poorly defined absorptions at 2976 ± 3 and 2830 ± 5 cm\textsuperscript{-1} arose from the \textit{v\textsubscript{as}(OCH\textsubscript{2})} and \textit{v\textsubscript{as}(OCH\textsubscript{3})} stretching bands at the terminal methoxy groups [47]. The following four IR absorption bands were assigned to the methylene stretching modes: 2949 ± 4 cm\textsuperscript{-1} (\textit{v\textsubscript{as}(OCH\textsubscript{3}))}, 2923 ± 2 cm\textsuperscript{-1} (\textit{v\textsubscript{as}(OCH\textsubscript{2}))}, 2892 ± 4 cm\textsuperscript{-1} (\textit{v\textsubscript{as}(OCH\textsubscript{2}))}, and 2791 ± 1 cm\textsuperscript{-1} (\textit{v\textsubscript{as}(OCH\textsubscript{2}))} [47,48]. The spectra of 7 adsorbed on the Au/SiO\textsubscript{2} surface were compared to a spectrum of a SAM of an OEG-terminated perdeuterated alkanethiol on Au [48–50] (Fig. 2). In both molecules, the OEG units were the same and, as seen in the scheme in Fig. 2, only those fragments gave absorptions in CH stretching mode region. Low intensities of the PMIRRAS spectra of 7 adsorbed on Au/SiO\textsubscript{2} in comparison to OEG-terminated alkanethiol on Au may indicate lower surface coverage of 7 on SiO\textsubscript{2} and/or different packing of silane and thiol molecules in the SAM.

In the CH stretching modes region, of the monolayer of 7 on the Au/SiO\textsubscript{2}, the \textit{v\textsubscript{as}(OCH\textsubscript{3})} mode at 2879 cm\textsuperscript{-1} gave the strongest absorption band. By contrast, in monolayers of various hybrid OEG alkanethiols adsorbed on the gold, the strongest absorption originated from the \textit{v\textsubscript{as}(OCH\textsubscript{2})} mode at 2890 cm\textsuperscript{-1} [49,50]. This indicated differences in the orientation of OEG fragment in SAMs of 7 on SiO\textsubscript{2} and its thiolate analogues on gold. The vector of the transition dipole moment of the \textit{v\textsubscript{as}(OCH\textsubscript{2})} mode at 2879 cm\textsuperscript{-1} is oriented perpendicular to the long axis of the OEG chain, whereas the transition dipole vector of the \textit{v\textsubscript{as}(OCH\textsubscript{3})} mode at 2890 cm\textsuperscript{-1} lies parallel to this axis [47]. The enhancement of the \textit{v\textsubscript{as}(OCH\textsubscript{2})} mode at 2879 cm\textsuperscript{-1} indicated that the long axis of the OEG chain had a large tilt towards the surface normal suggesting a poor packing of this part of the molecule in the self-assembled monolayer of 7 on the Au/SiO\textsubscript{2}. 

**Fig. 1.** C 1s high resolution XPS-spectra of 7 on the Si/SiO\textsubscript{2} surface.

**Fig. 2.** PMIRRAS spectra in the CH stretching region of monolayers of 7 on Au/SiO\textsubscript{2} after 3 h (dotted line), 24 h (dashed line) and 48 h (solid line) of self-assembly and PMIRRAS spectrum of SAM of hexaethylene glycol-terminated per-deuterated alkanethiol adsorbed on Au (thick solid line, data are taken from [49]).
Si–O–Si modes were analyzed in the PM IRRA spectra in 1500–900 cm⁻¹ region for a monolayer of 7 on the Au/SiOₓ using also their second derivatives (Fig. 3).

The PM IRRA spectra were dominated by two strong, superimposed absorption bands arising from the transverse and longitudinal ν₃(Si–O–Si) modes in the 10 nm thick SiOₓ substrate film on the Au surface (Fig. 3A) [38,51]. The hybrid compounds 7 and 8 also absorbed the IR radiation in this region complicating the analysis of the monolayer. The PM IRRA spectra of SAMs showed an increase in the intensity at 1220–1100 cm⁻¹ (Fig. 3). The second derivative of the PM IRRA spectra allowed the determination of the number and frequencies of the IR absorption modes in the SAM of 7 (Fig. 3B). It had minima at 1353, 1203, 1179, 1158, 1129 and 961 cm⁻¹. In order to identify the modes originating from 7, the PM IRRA spectra were first normalized and the difference spectrum between monolayers of compound 7 on SiOₓ and the background spectrum (bare SiOₓ) were calculated (Fig. 3C). The absorption at 1353 cm⁻¹ originated from the CH₂ wagging modes in the amorphous, disordered phase of OEG chains [47,49]. After 24 h of the reaction, a very weak absorption around 1330 cm⁻¹ appeared in the spectrum of the monolayer. The OEG part of 7 gave the CH₂ rocking mode at 961 cm⁻¹. The presence of these two modes in the PM IRRA spectra indicated that a fraction of OEG chains had gauche conformation. The presence of gauche conformations suggested that some OEG chains in the monolayer of 7 adopted a helical conformation [50,52]. Low intensities and the shape of the CH stretching modes, as well as the presence of very weak CH₂ wagging modes indicated that the OEG fragment in the monolayer of 7 existed in an amorphous state. The OEG chains were disordered and poorly packed. As shown in Fig. 3C, three absorption bands centered at 1223, 1203 and 1158 cm⁻¹ originated from the CF₂ and CC(F) stretching modes of the fluorinated alkane chain of the SAM of 7 [53–55]. The mode at 1223 cm⁻¹ was not resolved in the second derivative spectrum because it was superimposed on a strong absorption band of the SiO₂ substrate. This mode is due to the ν(CC(F)) stretching mode. It was found at 1226 cm⁻¹ in self-assembled monolayers of perfluorinated thiols [53]. The ν₁(CF₂) mode was located at 1203 cm⁻¹, whereas the mode at 1158 cm⁻¹ arose from the ν₃(CF₂) and δ(CF₂) modes [53,54]. A weak absorption around 1130 cm⁻¹ originated from the COC stretching mode of the OEG fragment of 7 [47,50], CC progression modes in the perfluorinated chains of 7 [54] as well as Si–O–Si stretching modes in the SiOₓ matrix [38]. The presence of a minimum at 1130 cm⁻¹ in the second derivative of the unmodified Au/SiOₓ substrate indicated that this absorption mode is due to the silica substrate. By contrast, only the second derivatives of monolayers of 7 showed a minimum at 1179 cm⁻¹. The origin of this band is not clear yet. It may arise from the asymmetric stretching mode of the O–Si–O lattice formed by 7 in the monolayer [36,57].

3.4. Contact angle measurements

After cleaning and treatment with UV/O₃, the Au/SiOₓ, Si/SiOₓ and BF33 surfaces were hydrophilic and their water contact angles were close to 0°. After the self-assembly of 7 on these surfaces, the water contact angle increased to ca. 80°, as listed in Table 1. The contact angle for the SAM of 7 on Au/SiOₓ was equal to (77 ± 3)° and was lower than the contact angles of modified Si/SiOₓ and BF33 substrates (82 ± 1)°. The measured contact angles were higher than contact angles reported for methyl-capped OEG terminated C₃₅-thioglates on gold or silver (63°) and methyl-capped-OEG-terminated-C₃₋₅-trichlorosilanes on SiOₓ (69°) [28,50,52]. Water contact angles of monolayers of perfluorinated silanes on the SiOₓ surface are higher and close to 110–120° [42,46,58,59]. Clearly, the measured water contact angles indicated that monolayers of the hybrid compound 7 adsorbed on various silica surfaces were terminated by OEG and not by fluorocarbon chains. The value of the contact angle depends on the OEG-termination and the architecture of the whole molecule. Interestingly, Hoffmann and Tovar found

a minimum advancing contact angle of ca. 81° for SAMs formed from methyl-capped-OEG-terminated-C11-dimethylchlorosilanes on silicon dioxide surfaces [29] (Table 1). Higher values of the contact angle (relative to OEG-terminated SAM on Au) reflected lower packing density and disorder in the monolayer of methyl-capped-OEG-terminated-C11-dimethylchlorosilanes [29]. In our case higher values of the contact angle in monolayers of 7 compared to other OEG-terminated films indicated that the methyl capped OEG-terminated silanes are less densely packed permitting some interaction of the perfluorinated alkyl chain with water during the contact angle measurement. The observed differences were smaller for SAMs of 7 on the Au/SiO2 substrate (77° compared to 81° and 82° for SAMs on Si/SiO2 and BF33) and indicated that this SAM has a higher degree of order than films prepared on the Si/SiO2 and BF33 surfaces.

3.5. SFM-measurements

SFM images were recorded in contact mode in water for bare Au/SiO2 and Au/SiO2 modified with silane 7 (Fig. 4). The bare Au/SiO2 surface was composed of grains which are in average 156 nm in diameter and 1–2 nm high. The surface roughness, determined as RMS over 5 μm × 5 μm surface, of the bare substrate was equal to (0.94 ± 0.04) nm. After 3 h of self-assembly of 7, the height of features increased to 3–5 nm and the RMS increased to (1.27 ± 0.12) nm (Fig. 4B). The topography of the monolayer was dominated by the topographic features of the substrate. The uniform coating of the substrate became apparent from the lateral force images of the bare and modified Au/SiO2 samples (Fig. 4C and D). Local friction forces decreased in the monolayer of 7 chemisorbed on Au/SiO2 surface. It is known that perfluorinated silanes reduce the local friction and the adhesion due to weakening of the interaction between the AFM tip and the sample [59]. In addition, Tizazu et al. [60] reported a weaker local friction for glass substrates modified with OEG-terminated silanes compared to bare oxidized glass substrates.

Interestingly, SFM images showed large difference in topography of the monolayer of 7 prepared on the BF33 substrate (Fig. 5). The RMS of a clean 5 μm × 5 μm BF33 surface is equal to (0.267 ± 0.004) nm. The BF33 surface is very smooth and practically flat on the atomic level. Already after 1 min of the self-assembly of 7 the RMS increased to (1.157 ± 0.131) nm.

New features of a height 2.9–5.4 nm appeared on the SFM image (Fig. 5A). Longer self-assembly times caused further changes in the topography and roughness of the glass surface. In the film produced after 10 min self-assembly of 7, the density of surface aggregates increased. The height of the features ranged from 7.2 to 13.8 nm and the RMS increased to (4.0 ± 1.0) nm. After 1 h of self-assembly, a densely packed film was formed from 1.1 nm × 0.6 nm large aggregates. Their height increased to 29.2 nm while the RMS rose to (8.07 ± 0.29) nm. Similar changes in the topography and roughness were observed for monolayers of 7 on Si/SiO2 surfaces (data not shown). The RMS of the bare Si/SiO2 surface increased from (0.463 ± 0.029) nm to (8.090 ± 0.106) nm after 4 h of self-assembly of 7. The length of a molecule can be estimated by increments for each group. The hybrid compound 7 contains two CH2 groups, each of it is 0.126 nm long, 10 CF2 units each of it is 0.13 nm long, the terminal methyl group which is 0.153 nm long, and 6 ethylene glycol units of variable length. The incremental length of the ethylene glycol units depends on the chain conformation and is equal to 0.278 nm in helical and 0.356 nm in planar conformation [50]. Therefore, the expected length of the stretched molecule of 7 varies from 3.373 to 3.841 nm for helical or planar conformation of the OEG chain, respectively. Therefore, the height of the observed structure exceeded the length of the hybrid molecule 7 indicating that oligomers or multilayers were formed in these regions.

Clearly, adsorption of 7 lead to the formation of non-uniform, multilayered films on BF33 and Si/SiO2 surfaces. This can be caused by the attachment of oligomers to the surface, which might be formed in solution by hydrolysis and polymerization of compound 7 and/or 8. Such larger siloxane species might also

Fig. 4. SFM topography contact mode images in water of (A) bare Au/SiO2 and (B) monolayer of 7 after 3 h of self-assembly on the Au/SiO2 surface. SFM friction images with lateral force mode of (C) bare and (D) modified Au/SiO2 surface.
physically adsorb on solid surfaces. Bunker et al. [59] and Pellerite et al. [58] observed also that perfluorinated silanes formed aggregates on Si wafers. The size of aggregates depended on the self-assembly duration. Pellerite et al. [58] prepared a perfluorinated silane on Si wafers by immersion in heptane. The height of the used trichloro-1H,1H,2H,2H-perfluorododecylsilane adsorbed on the Si surface varied from 1.5 to 6.0 nm and 1.5 to 15.0 nm in films produced during 1 and 60 min of adsorption, respectively [58].

By contrast, the adsorption of 7 on the Au/SiOx surface lead to the formation of well-defined monolayers. Our results suggest that the difference in the film quality was rather caused by the nature and/or surface quality of the substrate as the same conditions for cleaning and monolayer formation were applied to each sample. The BF33 samples consisted of 81% SiO2, 2% Al2O3, 4% Na2O/K2O and 13% B2O3 and was atomically smooth. The Au/SiOx surface is composed of grains and is not smooth on the atomic level.
4. Conclusions

In this paper the successful synthesis and monolayer properties of a new trichlorosilane 7 and dichlorosilane 8 are reported. Despite the fact that the reaction mixture contained the monomer (7) and the dimer (8), it was possible to form self-assembled films on various silica surfaces. The thickness, hydrophilicity and orientation of the hybrid compound 7 in self-assembled films depend on the nature of the used substrate. Scheme 3 shows schematically the molecular order in films of 7 self-assembled on Au/SiO\(_x\) surface as well as Si/SiO\(_x\) and BF33 surfaces.

SFM measurements of the film thickness indicated clearly that a monolayer of 7 was formed on the Au/SiO\(_x\) surface. Topography images as well as PM IRRAS showed that the monolayer was uniform and ordered at the molecular level as summarized in Scheme 3A. The OEG units exist in the amorphous phase. Long self-assembly times on the Au/SiO\(_x\) surface (>24 h) lead to some rearrangement in the monolayers, namely a transition of a small fraction of OEG chains from the amorphous state to the helical conformation was observed. In comparison to the thiol analogues, the hybrid molecule 7 formed less dense and less ordered monolayers. The long axis of the OEG fragment of the hybrid compound 7 tilts preferably parallel to the plane of the SiO\(_x\) surface. The anchoring SiCl\(_3\) group is bulkier than the SH group adsorbing on the Au surface, therefore the expected packing density of silanes on the silica surface is lower than for thiols on gold. Interestingly, a new band at 1179 cm\(^{-1}\) appeared in the PM IRRAS spectra of monolayers of 7 when self-assembly exceeded 24 h. This band is associated with the asymmetric stretching mode of Si—O—Si groups in the silica lattice of the monolayer. In silica films prepared via the sol-gel method it was observed at 1180 cm\(^{-1}\) [61]. Indeed, trichlorosilane groups of 7 may polymerize to form a lattice of silanes in the adsorbed film which lies parallel to the surface of the solid surface (Scheme 3A). This reaction may be responsible for the formation of well-defined pattern in the monolayers of 7 on the Au/SiO\(_x\) if self-assembly is carried out over relatively long times.

By contrast, the self-assembly of 7 on the Si/SiO\(_x\) and BF33 surfaces leads to the formation of films with poorly-defined packing and structure as shown in Scheme 3B. SFM measurements showed clearly that the self-assembled films of 7 on the Si/SiO\(_x\) and BF33 surfaces were inhomogenous and their thickness corresponded to length of 2–4 molecules of 7. The process of adsorption is fast compared to the adsorption of 7 on Au/SiO\(_x\). In this case the polymerization reaction of silanes seems to be responsible for a formation of disordered films. Interestingly, the chemisorption of 7 to the well-defined, almost atomically flat Si/SiO\(_x\) substrates is inefficient. This result suggests that the adsorbing molecules 7 and 8 require larger area than the distance between two anchor points on the silica lattice provides. The surface roughness of the Au/SiO\(_x\) substrate is significantly larger. The contained defects may provide sufficient space to accommodate a dense packing of 7 and formation of ordered monolayers. This is an important technological finding, which may facilitate controlling the order in the adsorbing monolayer via the control of the surface roughness of the silica surface. Initial tests of cell adhesion were done on silica 7 and 8 films modifying glass and silica surfaces. These results are shown in Supporting Information S13.
